REPORT OF COOPERATIVE RESEARCH ON INSECT CONTROL IN FARM STORED
GRAIN

No. 12 Period--April 1 to June 30, 1944

Compiled by R. T. Cotton, Entomologist
Cereal and Forage Insect Investigations
Bureau of Entomology and Plant Quarantine
U. S. Department of Agriculture
Manhattan, Kansas

The material in this report consists largely
of unpublished data and should be kept confidential.
It is made available in its present form for the
convenience of the various State and Federal
Agencies concerned with the preservation of stored
grain from insect damage.

WHEAT STORAGE

Condition of Wheat in Storage at Experimental Sites*

The regularly quarterly samples were taken from the bins at the Hutchinson, Kans., and Jamestown, N. D., experimental wheat storage projects during April and May and each sample was examined to determine the insect population. Table 1, which gives the comparison of the infestations at the Hutchinson and Jamestown sites since their establishment in 1941, shows that the insect populations at Hutchinson in April were the lowest observed since April 1943. At Jamestown the insect infestation has remained at a very low level throughout the entire storage period.

* - Reported by H. H. Walkden and R. B. Schwitzgobel, U. S. Department of Agriculture, Bureau of Entomology and Plant Quarantine in Cooperation with the Bureau of Plant Industry, Soils and Agr. Engineering.

The five species of stored grain insects found in the quarterly samples are listed below together with their comparative abundance.

<u>Species</u>	<u>Average number per 1000-gram sample</u>
1. Flat grain beetle (<u>Laemophloeus minutus</u> Oliv.).....	0.21
2. Lesser grain borer (<u>Rhyzopertha dominica</u> F.).....	0.13
3. Long-headed flour beetle (<u>Latheticus oryzae</u> Waterh.)....	0.13
4. Sawtooth grain beetle (<u>Oryzaephilus surinamensis</u> L.)....	0.10
5. Red flour beetle (<u>Tribolium castaneum</u> Hbst.).....	0.02

Distribution of Insect Populations in Stored Wheat

In order to determine the intra-bin distribution of insect populations, a separate examination of each of the individual probe samples composing the average sample has been made for each of the past four quarterly samplings.

The results of the April examinations are presented in tables 2 and 3. The data from 48 bins are included in these tables. No insects were found in samples from 96 bins and the data from one bin was omitted from the table since the infestation in that bin developed in spoiled wheat caused by a roof leak.

The intensities of infestation ranged from zero to 3.2 insects per 1000-gram sample in 1000 bushel steel bins; zero to 0.4 in 1500 bushel wood bins; and zero to 3.4 in 2740 bushel steel bins. In the 1000-2000 bushel bins 63 percent of the insects were taken in the center sample, while 25 percent were found to occur in the south portion of the grain. In 2740 to 4000 bushel bins, 46.8 percent of the population was found to be in the upper center sample and 20.7 percent was taken in the upper south sample.

A summary of the distribution of the insect populations within 1000 and 2740 bushel bins for the past four quarterly samplings is presented in tables 4 and 5 respectively.

During most of the year more than half of the insects were taken in the center and south samples in 1000 bushel bins. In August the population was well distributed throughout the grain as a result of the high summer temperatures which permeate the entire grain mass in bins of this size.

In 2740 bushel bins more than half of the insects were taken from the center and south portions of the grain each time the bins were sampled. Seventy-five percent of the time most of the insects were found in the upper half of the bins of this capacity.

The knowledge of the distribution of the insect populations within the bins for the various seasons of the year is an aid in developing an adequate sampling technique for the successful storage of grain in 1000 to 4000 bushel steel bins. It is evident from this study that samples taken in the center and south parts of the bins can be relied upon to reveal the presence of insects and indicate the maximum intensity of the infestation at any time of the year.

Effect of Different Management Practices on Insect Populations in Wheat Stored in Ever-Normal Granary Type Bins

During the past quarter, winter temperatures have reduced the insect population to such a low point that differences between the various management practices is scarcely discernible. The highest populations in April occurred in the untreated bins as shown in table 6, which gives the comparison of insect infestations in wheat stored under different management practices since the establishment of the Hutchinson site.

Winter Mortality of Insect Populations in Wheat Stored in
Ever-Normal Granary Type Bins

Mortality in the Natural Populations.

Two methods have been employed to study the effect of winter temperatures on the populations of stored grain insects in ever-normal granary type bins. In the first study a series of five 1000-bushel steel bins and eight 2740-bushel steel bins were sampled monthly from October 1943, to April 1944, inclusive. The data from these samples are presented in table 7. The mortality rate was highest in the unpainted 2740-bushel bins. The wheat in these two bins was of less than 11 percent moisture content while that of the wheat in the other 11 bins ranged between 11 and 12 percent.

It may be noted from table 7 that the insect mortality was least in unpainted 1000-bushel bins, as compared with that in the other bins under observation. The lesser grain borer, which has been the most serious pest to stored grain at this site, survived the winter near the south wall in these two unpainted 1000-bushel bins but was not found to be present in any of the other three groups of bins after the January sampling. It may also be noted from table 7 that during the sampling period the lesser grain borer population in white 1000-bushel bins remained very low and none were able to maintain themselves in white 2740-bushel bins.

Mortality of Introduced Insects Confined in Cages.

In order to obtain additional information on the effect of winter temperatures on insect populations in stored wheat, approximately 1600 insects, representing six common stored grain species, were placed in check capsules and put in the center of a 2740-bushel steel bin about six feet below the grain surface. The insects were confined in wire cages containing whole grain and flour. They were placed in the bin on November 15, 1943; removed at 15-day intervals for determining the rate of mortality; and the survivors replaced in the grain after each examination. The results of this experiment are presented in table 8.

It may be noted that a mortality of from eight to fifty percent occurred during the first two-week period. This may have been due to differences in moisture content of the grain in which the test insects were reared and that of the grain in the bin, since the temperature of both media was the same. By the first of February practically all of the lesser grain borers, rice weevils, and flat grain beetles were dead at which time the temperature of the grain at the point where the cages were located was 61 degrees F. By May 1, only one surviving sawtooth grain beetle was noted and on that date the grain temperature was 46 degrees F.

In comparing the rate of mortality in native and introduced insect populations as given in tables 7 and 8, it would appear that the native population was reduced more rapidly than the introduced population. Actually, the mortality rate was about the same for both groups. This can be explained by the fact that the native population was determined on the basis of an average sample from the bin under observations, whereas, the introduced insects were placed in the warmest part of the bin (center of grain mass).

Study of Fluctuation of Insect Populations in Wheat
Stored in Ever-Normal Granary Type Bins

During the past year the fluctuation of insect populations in wheat located in the upper southwest quadrant was studied from samples taken from center, south, southwest, and west portions and southwest surface of a series of steel and wood bins. In the 1000-bushel steel bins and the 1500-bushel wood bins a five-foot grain probe was used to sample the upper half of the bin while a seven-foot trier was used in 2740-bushel steel bins.

A total of 55 bins, including 24 1000-bushel steel bins, 28 2740-bushel steel bins and 3 wood bins, from the management series were used for this work. A record was made of the number of each species of insects taken from the five separate sampling locations for each examination. Near the beginning of the sampling period, June 10, 1943, samples were taken from the five locations in each bin and determinations made for fat acidity and germination. These tests were repeated for a similar set of samples taken January 1, 1944, (data not yet received).

A summary of the data obtained in this study are presented in tables 9, 10, and 11. Six species of stored grain insects were found in samples taken from this series of bins. However, the numbers of rice weevils and long-headed flour beetles are not included in the tables since their abundance was practically negligible. It may be observed from the tables that the flat grain beetle was taken in greater numbers than the other three species in steel bins. The maximum intensity of infestation in the wood bins was attained by the lesser grain borer with the red flour beetle ranking second.

The data indicate that the branbug populations reach their greatest intensity in August and September in steel bins but not until October and November in wood bins. The maximum population of the lesser grain borer occurs in October in both steel and wood bins.

Control of Insects in Farm-Stored Grain

In cooperation with the Reno County Agricultural Conservation Committee, work has been initiated on the control of insects in farm-stored grain as outlined in the program of research for 1944. Farmers were found to be willing and anxious to cooperate in this project. They were unanimous in the opinion that there was a pressing need for information on the control of insects in farm-stored grain, especially in wooden farm granaries where the wood-boring species, such as the cadelle (*Tenebroides mauritanicus* L.), present a serious problem.

After making a survey of the many bins offered for this investigation, eight farms were selected as having granaries suitable for the proposed experimental work. A total of 20 empty wooden grain bins were thus made available for the projected treatments. The immediate objective was to apply various materials to the interior walls of wooden farm granaries in order to control existing infestations of the wood-boring species of stored grain insects and also to prevent re-infestation after the bins were filled with grain.

Preliminary tests of different materials in small model bins were made by Dr. R. T. Cotton at Manhattan, Kansas. As a result of these tests certain materials proved to be effective in preventing the cadelle from boring holes in the wood of the miniature bins. It was desired to test the efficiency of these and other promising materials under farm conditions. The various materials used in this work are listed below:

1. K1127 2(2(2,4,5,6,-tetrachlorophenoxy)ethoxy)ethyl chloride*
(5% in deobase oil)
2. K208 phenothrixin* (5% in deobase oil)
3. K655 B(B(4-chlorophenoxy)ethoxy)ethyl chloride*
(5% in deobase oil)
4. Deobase oil
5. Dormant tree oil spray. (recommended by Farrar, Flint, and Winburn for the treatment of wooden granaries.)

6. Termitox (pentachlorphenol) (20% in deobase oil.

7. DDT (dichloro-diphenyl trichloroethane) (6% in deobase oil).

Note: DDT was first dissolved in ethylene dichloride and the resulting solution added to the deobase oil.

8. Whitewash. Formula: hydrated lime 50 pounds
casein glue 5 pounds
water to make desired consistency

(Recommended in National Lime Association Bul. 304-D)

(Recommended in Farmers' Bulletin 1452)

For the first coat the stock paint was thinned with two-fifths its volume of turpentine; the second coat with two-fifths its volume of linseed oil. Naphtha was added in each instance to thin for use in a paint spray gun.

10. Red paint. Sherwin-Williams red paint No. 367.

Formula:	Venetian red	67%
	Zinc oxide	4%
	Magnesium sulfate.	29%

11. Sisalkraft paper lining.**

* - Materials supplied by the Dow Chemical Co.
** - Materials supplied by the Sisalkraft Co.

All of the liquid materials were applied to the bin walls with a paint spray gun at a pressure of 40 pounds. The compressed air fumigation apparatus was adapted for use in this work.

In order to evaluate the efficiency of the several materials used in treating the interior walls of wooden farm granaries, it was necessary to set up a method of determining the extent of damage by wood-boring species at the time the treatment was applied; and also to be able to detect any additional damage subsequent to the application of the treatment. To do this a vertical area one foot wide was marked off on the bin wall and horizontal lines at one-foot intervals were laid off beginning twelve inches above the floor and extending to the top of the bin wall. Thus, areas one foot square were delineated. The number of holes in each area were counted and recorded for each of the walls receiving different treatments with the exception of those walls which were sprayed with whitewash, white lead, and red paint. The whitewash and paints filled the holes sufficiently so that any new holes can be detected easily. The summary of the counts made in the above manner is given in table 12.

Table 12:--Extent of damage by wood-boring species of stored-grain insects to walls of wooden farm granaries, Reno County, Kansas, May, June, 1944.

Location	Height of: bin wall (feet)		Number of counted	Number of holes per sq. ft.		
				Maximum	Minimum	Average
Bacon Farm SW bin	:	7	:	7	:	125
	:	:	:	:	:	31
Bacon Farm SE bin	:	7	:	35	:	116
	:	:	:	:	:	2

	:	:	:	:	:	0
Gump Farm	:	6	:	6	:	27
	:	:	:	:	:	3
Nicklaus Farm SE bin	:	11	:	22	:	121
	:	:	:	:	:	0
Nicklaus Farm NE bin	:	11	:	22	:	64
	:	:	:	:	:	0
Nicklaus Farm SW bin	:	11	:	22	:	81
	:	:	:	:	:	0
Nicklaus Farm NW bin	:	11	:	22	:	15
	:	:	:	:	:	0
Goodenough Farm	:	7	:	35	:	2
	:	:	:	:	:	0
Swanson Farm E bin	:	6	:	24	:	127
	:	:	:	:	:	0
Swanson Farm E boxcar	:	7	:	14	:	23
	:	:	:	:	:	0
Swanson Farm W boxcar	:	7	:	7	:	36
	:	:	:	:	:	0
Phillips Farm boxcar	:	7	:	28	:	123
	:	:	:	:	:	0

The number of holes ranged from zero to 211 per square foot of wall area in those bins in which counts were made. No damage was observed to the floors. The amount of damage appears to be related to the level to which the bins had been filled in previous years, since the greatest concentration of holes followed rather definite contours along the bin walls.

No indication of the number of cadelles remaining in the bin walls could be obtained by inspection, although a number of both larvae and adults were observed while the bins were being prepared for treatment.

In order to determine any immediate effect of the various treatments, the bins were inspected a few days after the treatments were applied, and the comparative number of dead insects were noted. Few dead insects were found except in those bins which had been treated with DDT. In bins treated with this material there were large numbers of dead cadelle adults and larvae on the floors at the junction of the floor and wall. It is possible that other treatments killed the insects before they could emerge from their burrows and that DDT drives them out to die. The results with DDT were astonishing. Some 8,000 dead adults were swept up on the floor along 10 linear feet of wall space. The DDT evidently continued to kill for at least a month after application, since repeated inspection of treated bins revealed dying cadelles which had emerged from the walls.

It is of interest to note that several farmers in this vicinity have used whitewash as a wall treatment for farm granaries. In most cases the whitewash had scaled off in places leaving bare wood exposed. In all bins observed such unprotected areas were subject to attack by the cadelle, but wherever the whitewash was intact, no borings were found.

In the past it has been commonly recommended that granaries should be thoroughly cleaned before applying treatment. Since it is virtually impossible to remove all grain from cracks and crannies, it was decided to clean up some of the bins as well as possible and leave others in the condition they were found after the grain had been removed by the owner.

It was found that two coats of whitewash or paint were required to secure complete coverage and partial filling of the cadelle borings in the walls.

Most wooden farm granaries are rather loosely constructed making fumigation difficult. In order to make such bins reasonably gas tight, the walls of one bin on the Henderson farm were lined with sisalkraft paper. The other bin in this granary was left untreated. After filling with the present wheat crop it is planned to fumigate both bins to determine any differences in the dosage of fumigant required for successful fumigation.

Magnesium Oxide for Seed Treatment*

The recent increased interest in inert and chemical dusts for the protection of wheat from insect attack has led to the investigation of the insecticidal action of a number of materials both poisonous and non-poisonous. In previous reports from this laboratory the insecticidal properties of a number of disinfectant dusts have been given together with data on a number of other dusts not recommended as disinfectants but reported to be useful for protecting grain from insect damage.

The insect pests of stored grain feed on relatively dry foods and obtain much of their moisture requirements by breaking down or oxidizing these dry materials. The conservation of moisture is an important factor in their existence. It is thought that dusts cause the death of these insects by dehydration.

There are several theories to account for the desiccation caused by fine dusts coming in contact with the insect body.

1. Close contact of the dust with the insect body causes the body water to be conducted by capillary action to the air where it is evaporated. The drier the air, the faster the evaporation and consequently the more rapid the death of the insect.
2. By increasing the body surface of the insect, the evaporation surface is increased and desiccation results.
3. Insects have a "water proof" fatty film on their relatively pervious shell. Contact with hard, sharp, crystalline particles breaks the film. Drying of the insect naturally follows. Dusts of the diamond class of hardness (10 on the Moh scale) are most effective. They must have a hardness of at least 6.5 on the Moh scale to be effective. The dust must be fine with particles mostly under 10 mu. and a large proportion between 1 and 5 mu.

Many dusts are effective under dry atmospheric conditions and in previous tests, lime, sulphur, wood ashes, and even soy bean flour show good insecticidal value in 12% moisture wheat.

Particle size of the dust would appear to be of considerable importance. In 1929 F. Zacher suggested the use of magnesium oxide against the granary weevil and other stored product pests such as Spermophagus subfasciatus, Dermestes murinus L. and Ephestia kuhniella. In the following year F. Zacher and G. Kupiske reported the successful use of oxides and carbonates of magnesium, manganese, zinc and copper when in a fine dust. Compounds of silicon (such as sea sand) were also found effective when in a fine state. H. Schneider in 1932 reported good results with both magnesium oxide and magnesium hydroxide. H. Kreig in 1933 also reported on the insecticidal value of magnesium oxide. Low temperature and high humidity retard the action of these dusts.

In response to our request, Dr. R. C. Roark sent us a sample of magnesium oxide (ID No. 7363, No. 1) of which the surface-mean particle diameter was less than 0.25 micron. This is finer than the dust known as "Almicide".

Five-hundred gram samples of 12.5% moisture wheat in duplicate were treated with this dust at dosages of .05, 0.1, and 0.2 percent by weight. 200 rice weevil adults were added to each sample and to two untreated or check samples.

Thirteen days later the samples were examined with the following results:

Table 13: -- Effectiveness of MgO₂ in protecting 12.5% moisture wheat from rice weevil attack.

Sample number:	Dosage magnesium oxide by weight	Condition of rice weevil 13 days after treatment	Number alive	Number dead
1 :	.05%	:	7	193
2 :	.05%	:	0	200
3 :	.1%	:	0	200
4 :	.1%	:	0	200
5 :	.2%	:	0	200
6 :	.2%	:	0	200
7 :	Check	:	197	3
8 :	Check	:	200	0
:	:	:	:	:

Two additional series of samples were prepared using the flour beetle, tribolium confusum, and the lesser grain borer, as test insects. At the end of 5 days they were examined with the results shown in table 14.

Table 14: -- Effectiveness of MgO_2 in protecting 12.5% moisture wheat from the attack of the flour beetle and the lesser grain borer.

Lot No.	: Dosage of MgO_2 by weight	Condition of insects after 5 days			
		Flour beetle		Lesser grain borer	
		No. alive	No. dead	No. alive	No. dead
1	0.05%	99	1	7	93
2	0.05%	65	35	0	100
3	0.1%	0	100	0	100
4	0.1%	0	100	0	100
5	0.2%	0	100	0	100
6	0.2%	0	100	0	100
7	Check untreated	100	0	100	0

As shown by the data of table 14 wheat treated with magnesium oxide at the rate of .1% by weight is quickly freed of all insect life. No emergence has been observed in the above samples.

The results of germination tests conducted with treated seed of 12.5% moisture content are given below.

Table 15: -- Effect of magnesium oxide treatment of 12.5% moisture wheat on viability.

Period of exposure:	Treatment	Percent germination--Average of 2 tests
2 weeks	:No treatment:	93.5
do	: .05% MgO_2 :	93
do	: .1% MgO_2 :	95
do	: .2% MgO_2 :	98
4 weeks	:No treatment:	87
do	: .05% MgO_2 :	92
do	: .1% MgO_2 :	90
do	: .2% MgO_2 :	89

It is interesting to note from the above data that the germination of the treated seed is better than that of the untreated seed in nearly all cases.

To more fully evaluate the protective action of the dust, the tests were repeated with 14% and 16% moisture wheat. Results of these tests are given in table 16.

Table 16: -- Effectiveness of MgO_2 in protecting high moisture wheat from the attack of the rice weevil from May 18 to June 20, 1944. 100 adult rice weevil added to each 500 gram sample of wheat.

:Moisture:		:Survival of rice weevil after				:No. of progeny at end	
Lot:content	No.:of wheat	Treatment:	1 week	2 weeks	3 weeks	4 weeks	:of 5 weeks
1 : 14%	: .05% MgO_2	: 86	: 79	: 69	: 65	: 653	
2 : 14%	: .1% MgO_2	: 29	: 17	: 11	: 8	: 914	
3 : 14%	: .2% MgO_2	: 10	: 6	: 3	: 1	: 876	
4 : 14%	: Untreated	: 98	: 98	: 95	: 90	: 546	
5 : 16%	: .05% MgO_2	: 94	: 91	: 83	: 81	: 585	
6 : 16%	: .1% MgO_2	: 82	: 66	: 55	: 41	: 226	
7 : 16%	: .2% MgO_2	: 74	: 51	: 40	: 21	: 157	
8 : 16%	: Untreated	: 100	: 95	: 94	: 88	: 854	
:	:	:	:	:	:	:	

From the data of table 16 it is evident that as the moisture content of the wheat increases the effectiveness of the dust decreases, and that with wheat of 14% moisture or above the material is not effective. Fourteen percent is the upper moisture limit at which wheat can be safely stored, and most seeds are stored with a moisture content considerably lower than that.

Germination tests were conducted with treated 14% moisture wheat with the results shown in table 17.

Table 17: -- Effect of magnesium oxide treatment of 14% moisture wheat on viability.

Period of exposure:	Treatment	Percent germination--Average of 2 tests
4 weeks	: No treatment	: 88
do	: .05% MgO_2	: 88
do	: .1% MgO_2	: 90
do	: .2% MgO_2	: 93
:	:	

As was the case with the 12.5% moisture wheat, the viability of the 14% moisture wheat was improved in most cases by the treatment with magnesium oxide.

Tests with "Almicide" for the Protection of Rough Rice*

With the cooperation of Dr. E. C. Tullis, Pathologist of the U. S. Dept. of Agriculture, stationed at Beaumont, Texas, tests were conducted to determine the efficacy of Almicide in protecting rough rice from infestation by insects.

One-pound samples of rough rice in quadruplicate were treated with Almicide at the rate of .1%, .2%, and .275% by weight. The samples in small burlap bags were placed in a rice mill in Beaumont, Texas, on November 29th, together with 4 bags of untreated rice. They were all exposed to insect infestation until the following April 11th at which time they were removed and shipped to Manhattan for examination.

When examined on June 20th the number of living insects per sample were recorded with the results shown in table 18.

Table 18: -- Development of insect infestation in 1-pound samples of rough rice after exposure to infestation in rice mill from November 29, 1943 to April 11, 1944.

Sample number:	Treatment	No. of living insects--Average of 4 samples					
		Rice weevil	flour beetle	Granary weevil	grain beetle	grain beetle	sawtooth beetle
1	Untreated	580	18	12	15	6	20
2	.1% by wt. Almicide	3	2	0	1	0	0
3	.2%	do	0	0	0	0	0
4	.275%	do	0	0	0	0	0

From the data of table 18 it is evident that Almicide affords excellent protection to rough rice at all dosages tried. In the samples that were treated at a dosage of .1% by weight a few living insects were present but no appreciable damage had been caused and the number of insects present was negligible. In the samples treated at the heavier dosages no insects were present. The untreated rice was heavily infested.

* - Reported by R. T. Cotton and J. C. Frankenfeld.

Effect of Common Grain Fumigants on Baking Qualities*

Little information is available with regard to the effect of grain fumigants on the baking quality of flour made from fumigated grain. Since carbon tetrachloride and related chlorides are currently being evaluated as grain fumigants it was felt desirable to investigate their effect on baking quality, and since mixtures of carbon tetrachloride and carbon disulphide are so commonly used, carbon disulphide alone and in combination with carbon tetrachloride was included in the tests.

Ten pound samples of wheat were fumigated in tightly stoppered glass flasks for a period of 1 week with dosages of the various fumigants of 50 lbs. per 1,000 bushels. This dosage represents the highest concentration that would be used under ordinary circumstances and is somewhat higher than would normally be used.

After fumigation, the various samples were allowed to aerate for two weeks. They were then milled and loaves baked from the resulting flours. A second series of samples will be allowed to aerate for two months after which they will be milled and a second baking made.

Results of the baking tests are shown in table 19.

The data of table 19 indicates that there is little effect on baking values as a result of fumigation with most of the fumigants tried. Carbon tetrachloride alone caused a significant loss in loaf volume and tetrachloroethylene imparted a slight odor. These effects were probably caused by retention of the fumigants by the flours. With longer aeration of the fumigated wheat these effects will probably disappear. Milling and baking of the second series of samples will settle this point.

* - Reported by R. T. Cotton and J. C. Frankenfeld in cooperation with Milling Department of Kansas State College.

Table 19:--Baking values of flour from wheat fumigated with various fumigants for one week and aerated for 2 weeks before milling.*

Sample number:	Fumigant used	Dosage : Pounds per bushels : M	Protein : Ash %	Moisture: time : vol. %	Mixing : Loaf Min. : cc	Texture: Color:	Remarks

3	Carbon tetrachloride	50	11.30 : 405 :	14.25 : 3.5 :	685 :	82-0 :	82cy : do
4	Trichloroethylene	50	11.15 : 398 :	14.70 : 3.5 :	755 :	82-0 :	80cy : do
5	Carbon disulphide-CCl ₄	50	11.30 : 398 :	14.35 : 3.5 :	760 :	82-0 :	82cy : do
6	(1-4) mixture	50	10.20 :	14.26 : 3.5 :	730 :	87-0 :	grey : slight odor

* - Average of two tests.

Effect of Nitriles on the Baking and Milling Qualities of Wheat*

It has previously been reported that fumigation of wheat with a 1-18-1 mixture of acrylonitrile, carbon tetrachloride and trichloroacetonitrile caused a deleterious effect upon the baking quality of flour made from fumigated wheat. These tests were made one week after fumigation. Additional tests were made two months later after the wheat had had an opportunity to become aerated. As indicated by the data of table 20 the baking values of the treated wheats appeared to have been recovered.

Table 20: -- Effect of fumigation with 1-18-1 mixture of acrylonitrile + carbon tetrachloride + trichloroacetonitrile on baking quality of wheat.

Sample number:	Treatment	Time of baking (after fum.)	Time of mixing	Absorption	Loaf vol.	Crumb color	Grain texture	Remarks
1	:2 gals. per M. bu.:	: 1 week.	: 3.7	: 66	: 773	: 80cy:	: 80-o	: No odor
2	:Check	: 1 week	: 3.0	: 66	: 945	: 83cy:	: 84-o	: do
3	:2 gals. per M. bu.:	: 2 months	: 3.3	: 65	: 713	: 82cy:	: 83-c	: do
4	:Check	: 2 months	: 3.3	: 65	: 680	: 81cy:	: 80-o	: do
5	:1 gal. per M. bu.:	: 1 week	: 3.4	: 66	: 775	: 80cy:	: 78-o	: do
6	:Check	: 1 week	: 3.2	: 66	: 895	: 80cy:	: 82-o	: do
7	:1½ gals. per M. bu.:	: 2 months	: 3.3	: 65	: 708	: 81cy:	: 80-o	: do
8	:Check	: 2 months	: 3.3	: 65	: 705	: 81cy:	: 80-o	: do

As a further check on the ability of the grain to recover from the effects of fumigation with the 1-18-1 mixture, a sample of wheat was fumigated for 1 week with a dosage of 2 gallons of the mixture per 1,000 bushels and allowed to aerate for 2 months. At the end of that period the grain was milled and baked with the results shown in table 21.

Table 21:--Effect of 1-18-1 mixture of acrylonitrile-carbon tetrachloride and trichloroacetonitrile on baking quality of wheat.

Sample number:	Dosage per M. bushels	Aeration period	Time of mixing	Loaf vol.	Crumb color	Remarks
1	: 2 gals.	: 2 months	: 2.8	: 800	: 83cy	: No odor
2	: Check	: 2 months	: 2.8	: 845	: 83cy	: do

From the above data it is evident that in this latter case the bad effects of the fumigant mixture (loss in loaf volume) were not overcome by aeration for a two-month's period. It is doubtful whether this mixture will be satisfactory as a fumigant for wheat intended for milling and baking.

* - Reported by R. T. Cotton and J. C. Frankenfeld in cooperation with the Milling Department of Kansas State College.

Reproduction of Granary and Rice Weevil in 12, 13,
and 14% Moisture Wheat and Corn at 65° F.*

In the last report we presented data relative to the survival of the granary and rice weevil at a constant temperature of 65° F. Due to the fact that emergence of progeny was not completed at that date, this information could not be included. Tables 22, 23, 24, and 25 give the biweekly reproduction at 65° F. in 12, 13, and 14% wheat of the granary and rice weevil.

In this series of tests, 50 adults instead of 100 were used in each lot. The reproduction in number of adults used is due to the fact that smaller quantities of wheat (100 grams) had to be used, owing to limited refrigerator space.

Reproduction occurred in all three moisture variant lots, and in both wheat and corn. As observed at higher temperatures, the rate of reproduction is influenced by the moisture content of the food, increasing as the moisture content is increased. This relationship holds true for both the granary and rice weevil, when reared in wheat or corn.

Development of larval stages of both the rice weevil and granary weevil is extremely slow at 65° F. so that in order to complete our records in a reasonable time, samples of grain exposed to oviposition by the weevils were removed at biweekly intervals and placed in incubators with a constant temperature of 80° F. and a relative humidity of from 70 to 80%. At a constant temperature of 65° F. the minimum development period of the rice weevil and granary weevil from egg to adult was observed to be 3 months.

* - Reported by R. T. Cotton and J. C. Frankenfeld.

Effect of Temperature and Moisture Content of Wheat upon
the Survival and Reproduction of the Granary and Rice Weevil*

Continuing our investigations on the effect of temperature and moisture upon the granary and rice weevil, we have inaugurated a series of tests at a constant temperature of 90° F., in which the moisture content of the wheat varies, at 1% intervals, from 9 to 14% inclusive. This series has been in progress for eleven weeks and the percentages of survival are summarized in table 26. Two replicate lots of 100 adults of each species are included in each of the moisture variant wheat series.

In general, as in previous tests, at lower temperatures, longevity of the adult weevils increases as the moisture content of the wheat is increased. A constant temperature of 90° F. is not conducive to longevity. The granary weevil appears to be longer lived than the rice weevil at this temperature.

Reproduction records for this series are not complete and will be included in a later report.

* - Reported by R. T. Cotton and J. C. Frankenfeld.

Effect of the Amount of Dockage on the Ability of *T. confusum* to Survive and Reproduce in Wheat of Various Moisture Content*

In Report No. 11 observations on this series of tests were reported covering the first five weeks that the tests were in progress. This report takes up the records beginning with the sixth week.

As previously reported two sets of tests, one at a constant temperature of 85° F. and the other at 90° F., were established in continuing our investigations on the effect of dockage on the ability of *T. confusum* to survive and reproduce in wheat. Tables 27 and 28 summarize the percentage of survival at weekly intervals, and the total number of progeny recovered for a period of 19 weeks.

With the exception of the 9% moisture wheat series, there is very little difference in the percentage of survival due to the amount of dockage present. In the 9% wheat, however, the percentage of survival increases with increased amounts of dockage. There is, however, a decided increase in the percentage of survival between the different moisture levels. Although this species is able to feed on practically moisture-free food, yet over extended periods of time a higher percentage of survival is obtained with a food of higher moisture content. The apparent decrease in survival as noted in the 8% dockage lots in both the 12 and 15% moisture series is not readily explainable. Undoubtedly some other factor is involved than those under control in these tests.

From the standpoint of reproduction, we have the same picture as was obtained in our earlier tests, i.e., as the percentage of dockage is increased, the total number of progeny produced, and able to complete development, increases. Also, as the moisture content of the rearing media is increased, the total number of progeny increases.

At 90° F. the percentage of survival likewise increases as the moisture content of the wheat is increased. Dockage, except in the 9% series, again having little or no effect on survival. Reproduction at all moisture levels increases as the amount of dockage present in the wheat is increased, and at a given dockage rate, increases as the moisture content of the wheat is increased.

Although the percentage of survival is slightly lower in the 90° F. series as compared with the 85° F., the total number of progeny is in general consistently higher in the 90° F. series. This is particularly true in the lots containing the larger percentages of dockage.

In the lots containing 1, 2, and 4% dockage in the 12% moisture series run at 90° F., the records are not complete. In these three lots, all of the adults had died after the 4th week. These lots were therefore restocked after the 4th week and will be carried on until they have reached the 19th week limit. There is no logical explanation for the high mortality noted above.
